Expert consensus on the perioperative management of patients with sepsis

Chinese Association of Anesthesiologists

Corresponding Author: Xiang-ming Fang, Email: xiangming_fang@163.com; Department of Anesthesiology, the First Affiliated Hospital, School of Medicine, Zhejiang University, Hangzhou, China

INTRODUCTION

Sepsis is defined as an infection associated with systemic manifestations of inflammation, which has become the most common complication in the perioperative period caused by severe burn/trauma and major surgical operation.[1,2] The incidence of sepsis in adults is estimated to be 149–240/100 000 per year, and that of severe sepsis and septic shock is 56–91/100 000 per year. In the last decade, the short-term mortality of sepsis has declined to around 20% in developed countries partly due to the international Surviving Sepsis Campaign (SSC), while the mortality remains very high (50%–80%) in 1–5 years after discharge from hospitals.[3–7] Thus, sepsis and its subsequent severe sepsis and septic shock are currently major issues in the field of medical and health care.

Control of infection, involving removal of infected and necrotic tissue, surgical drainage of abscess combined with early antimicrobial therapy, is essential to the successful treatment of sepsis.[8] Imbalance of pro-inflammation and anti-inflammation in septic patients is usually caused by the failure of infection control or the perforation of hollow organs. Fast exacerbation of sepsis constantly leads to circulatory and respiratory insufficiency and/or other viscera damage. Hence the risk of septic patients is very high during anesthesia. To improve the quality of clinical anesthesia and reduce the incidence of perioperative death and organ dysfunction in patients with sepsis, the Chinese Association of Anesthesiologists (CAA) set up a consensus committee consisting of 22 well-known Chinese anesthesiologists to draft a consensus on the perioperative management of patients with sepsis.

CLASSIFICATION OF RECOMMENDATIONS

Recommendations were classified according to the principles of ASA membership.[9] Firstly, the recommendations were designed as a questionnaire by the expert anesthesiologists. A questionnaire survey was conducted among the members of the CAA and the Youth Committee of the CAA (YCCA) at the annual meetings. The members should independently make a single choice to each recommendation from the options including 1 – strongly supported, 2 – supported, 3 – equivocal, 4 – opposed, 5 – strongly opposed.

Responses to the questionnaire survey from the members were analyzed, and were used to grade the recommendations into class I to V:

Class I: at least 50% of the responses are 1 – strongly supported;
Class II: at least 50% of the responses are 2 – supported, or 1 – strongly supported and 2 – supported;
Class III: at least 50% of the responses are 3 – equivocal, or no other option contains at least 50% of the responses;
Class IV: at least 50% of the responses are 4 – opposed, or 4 – opposed and 5 – strongly opposed;
Class V: at least 50% of the responses are 5 – strongly opposed.

Finally, the grade was signed at the back of recommendations to help the clinical anesthesiologists to use them.

DIAGNOSIS AND DEFINITION OF SEPSIS

Recommendations

1. The definitions of sepsis, severe sepsis and
septic shock were based on the principles of definition and diagnosis proposed by the International Sepsis Definitions Conference (class I).

In 2001, an international sepsis definitions conference was held jointly by the Society of Critical Care Medicine (SCCM), European Society of Intensive Care Medicine, ESICM), American College of Chest Physicians (ACCP), American Thoracic Society (ATS) and Surgical Infection Society (SIS). The proposed definition and diagnosis of sepsis, severe sepsis and septic shock have been applied in clinics and research institutions for decades (Tables 1 and 2). A recent retrospective study showed that about 12% of patients with severe sepsis did not meet two or more criteria of Systemic Inflammatory Response Syndrome (SIRS). Moreover, adjusted analysis revealed that the mortality of SIRS increased linearly with each additional criterion, without any transitional increase in risk at a threshold of two SIRS criteria. Thus, we do not hold that the diagnosis of sepsis, severe sepsis and septic shock was strictly adherent to two or more SIRS criteria. It is necessary to get a detailed medical history, clinical symptoms, signs and laboratory examinations (Table 1), then to make a clinical diagnosis after comprehensive evaluation.

### Table 1. Diagnostic criteria for sepsis

**Infection, documented or suspected, and some of the following:**

<table>
<thead>
<tr>
<th>General variables</th>
</tr>
</thead>
<tbody>
<tr>
<td>Fever (&gt;38.3 °C)</td>

<tr>
<th>Tissue perfusion variables</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hyperlactatemia (&gt;2 mmol/L)</td>
</tr>
<tr>
<td>Decreased capillary refill or mottling</td>
</tr>
</tbody>
</table>

**Sepsis-induced hypotension:**

- Lactate above upper limits laboratory normal
- Urine output>0.5 mL·kg⁻¹·h⁻¹ for more than 2 hours despite adequate fluid resuscitation
- Acute lung injury with PaO₂/FiO₂<250 in the presence of pneumonia as infection source
- Acute lung injury with PaO₂/FiO₂<200 in the presence of pneumonia as infection source
- Creatinine>2.0 mg/dL (176.8 µmol/L)
- Bilirubin>2.0 mg/dL (34.2 µmol/L)
- Platelet count<100×10⁹/L

**Coagulopathy** (international normalized ratio >1.5)

**Septic shock is defined as persistent arterial hypotension or hyperlactatemia in spite of adequate fluid resuscitation.**

**Table 2. Severe sepsis and septic shock**

- Severe sepsis is defined as sepsis-induced tissue hypoperfusion or organ dysfunction (any of the following thought to be due to the infection):

### PATHOPHYSIOLOGICAL CHARACTERISTICS OF SEPSIS

Sepsis and subsequent sepsis-related diseases are recognized as a group of clinical syndromes induced by trauma, pneumonia, suppurative cholangitis, suppurative peritonitis and severe acute pancreatitis. Clinical manifestations of sepsis vary among different patients, but the pathophysiologic process of sepsis is similar.

The occurrence and development of sepsis are mediated by various immune cells and inflammatory factors. In the early stage of sepsis, the immune system is over activated and mainly manifests as the uncontrolled.
systemic inflammatory response. The Toll-like receptors (TLRs) and the non-toll-like receptors (non-TLRs) expressed on host immune cells including monocyte/macrophages and neutrophils mediated the recognition of pathogen-associated molecular patterns (PAMPs) and/or danger-associated molecular patterns (DAMPs). In the late stage of sepsis, however, host gradually progresses to immunosuppressive state, showing that the response of immune cells to the pathogen is abate, primary focal infection is difficult to remove, and the secondary double infection and latent viruses replicate actively.[11,12]

The imbalance of immune and inflammatory response in the development of sepsis could inevitably cause the disruption of vascular endothelial barrier, tissue edema, hypotension, decrease of oxygen-carrying function of red blood cells, and thrombosis of microcirculation. Essentially, it causes tissue hypoperfusion, decrease of tissue oxygen supply, dysfunction of cellular oxygen metabolism, which leads to dysfunction of the nervous system, circulatory failure, respiratory dysfunction, hepatic/renal insufficiency, coagulation dysfunction, etc.[13-19]

PREOPERATIVE EVALUATION AND TREATMENT

Sepsis is lack of specific criteria of diagnosis in early stage, and it is likely to develop to severe sepsis or septic shock. Patients with sepsis often undergo emergency surgery, but anesthesiologists usually have inadequate time to evaluate these patients before the operation. Hence, preoperative analysis of organ function, medical history and surgical conditions of septic patients should be emphasized for the precise assessment of the risk of anesthesia and the effective therapy.

Assessment of organ function
The cardiovascular system

The impairment of the cardiovascular system is common in septic patients, which can subsequently develop to septic shock in severe cases. It has been reported that the incidence of cardiovascular dysfunction within 24 hours in septic patients is about 30%.[20] Moreover, the risk of anesthesia is related to the severity of cardiovascular dysfunction. Therefore, it is meaningful to assess the function of the cardiovascular system before surgery so as to identify early septic shock patients and provide early therapy.

Recommendations
1. Body temperature, skin color, urine volume, heart rate and blood pressure of septic patients should be observed closely to assess cardiovascular condition and determine septic shock early (class I).
2. At least two venous accesses should be implanted for fluid infusion in addition to the preparation of some micro-infusion pumps and vasoactive drugs including noradrenaline, adrenaline, vasopressin, dopamine, dobutamine and phenylephrine (class I).
3. Invasive artery blood pressure (IABP), central venous pressure (CVP) and blood lactate should be monitored to evaluate the effect of fluid management (class I).
4. Central or mixed venous oxygen saturation should be monitored to assess tissue perfusion of the patients (class III).
5. Cardiac ultrasound and test of FloTrac or PiCCO should be done to monitor fluid management (class II).

The volume status, cardiac function, tissue perfusion and vascular tension of the patients are evaluated to determine whether they have cardiac dysfunction or septic shock. In the early stage of shock, the patients often demonstrate clammy and pale skin, hypourcricia, increased heart rate and normal or increased blood pressure, etc. Hence, anesthesiologists must observe these symptoms so as to identify early septic shock before surgery. Once septic shock occurs, early goal directed therapy (EGDT) must be initiated. Referring to the international guidelines for the treatment of severe sepsis and septic shock proposed by the international surviving sepsis campaign (SSC guideline), targets for fluid management within 6 hours in patients with septic shock included: mean arterial pressure (MAP) ≥65 mmHg, CVP 8–12 mmHg, urine volume≥0.5 mL/kg per hour, SvO2≥70% and SvO2>65%.[21] It has been confirmed that EGDT could significantly decrease the mortality of septic shock patients.[21-23] IABP and CVP monitoring is necessary to evaluate the volume status and the effect of fluid management. Clinical studies[24-26] demonstrated that blood lactate was a standard marker for tissue infusion and the effect of fluid therapy, and the clearance rate of lactate was significantly related to the mortality of the patients. Recent multi-center clinical studies[12,27] found that fluid therapy targeted ScvO2>70% had no beneficial effect on the survival rate of patients with severe sepsis, which is consistent with the finding of River et al, a single center clinical study, indicating that fluid therapy targeted ScvO2>70% is beneficial for the patients with severe sepsis. Therefore, we still do not define the role of continuous monitoring ScvO2 in septic patients. As sepsis-induced cardiomyopathy and chronic heart disease are commonly associated with septic patients who are vulnerable to cardiac dysfunction,
In 2011, a panel of experts convened a conference and modified the definition of ARDS, which was published later in *JAMA* as the Berlin Definition given by the European Critical Care Medicine (ECCM). The updated definition of ARDS specified the acute time frame of ARDS (within 7 days of a known clinical insult or new or worsening respiratory symptoms), and erased the definition of ALI. In addition, the conference proposed 3 mutually exclusive severity categories of ARDS: mild (200 mmHg < PaO₂/FiO₂ ≤ 300 mmHg), moderate (100 mmHg < PaO₂/FiO₂ ≤ 200 mmHg) and severe (PaO₂/FiO₂ ≤ 100 mmHg). The standard of pulmonary artery occlusion pressure (PAOP) ≤ 18 mmHg was eliminated, while emphasizing differential diagnosis from heart failure and liquid overload. Moreover, meta-analyses suggested that the updated Berlin definition was strongly associated with the mortality of patients and could more accurately predict the outcome of ARDS as compared with the previous definition. Imaging examinations including chest radiography, chest CT and lung ultrasonography are beneficial for the assessment of lung injury and helpful to identify the type of lung injury (hydrothorax, lung consolidation and alveolar interstitial syndrome), which could enhance the sensitivity and specificity of diagnosis and guide the performance of mechanical ventilation. Moreover, lung ultrasonography is an imaging tool for detecting the occurrence of "spared area" in lung tissue (at least one intercostal space of normal lung tissue exists in the areas of alveolar-interstitial syndrome) that can differentiate ARDS from cardiogenic pulmonary edema.

### Renal function

Acute kidney injury (AKI) is due to inflammation reaction, endothelial injury and microcirculation disturbance, which were induced by sepsis. Studies revealed that 50% of patients with AKI were induced by sepsis in the ICU, suggesting that sepsis is the main cause of AKI. AKI is regarded as an independent risk factor of death in septic patients.

#### Recommendations

1. Urine volume, serum creatinine and urea nitrogen are routinely tested to evaluate the renal function before surgery (class I).
2. Preoperative hyperkalemia (>5.5 mmol/L) should be adjusted using glucose combined with insulin, calcium supplement, sodium bicarbonate and furosemide (class II).
3. Continuous renal replacement therapy (CRRT) is given
to the patients with severe renal function injury or renal failure while monitoring intermittent coagulation function to evaluate the risk of bleeding (class II).

Renal dysfunction, a clinical syndrome that often occurs in septic patients, is characterized by oliguria, increased serum creatinine and urea nitrogen, and even acid-base imbalance and hyperkalemia. Patients with abnormal electrolyte especially hyperkalemia (>5.5 mmol/L) should be treated before operation. Glucose combined with insulin can promote the transfer of potassium to reduce the concentration of serous potassium by enhancing the utility of glucose. Calcium supplements including calcium chloride and calcium gluconate which are able to stabilize cardiomyocytes, and can be used for the treatment of patients with hyperkalemia who are accompanied with abnormal electrical activity of myocardial cells and even fatal arrhythmia. Severe hyperkalemia combined with acidosis (pH<7.15) can be treated with sodium bicarbonate to promote the transfer of potassium into cells because of decreased concentration of serous potassium. Furosemide, loop diuretics, can be applied to patients with hyperkalemia who are combined with oliguria and fluid overload. In patients with severe renal function injury or renal failure, CRRT should be considered. More importantly, invasive operation is not recommended within 24 hours after heparinization. Activated clotting time (ACT) should be monitored if an operation is inevitable and protamine should be used to antagonize heparin.

Liver function
Liver injury is often ignored in the treatment of sepsis. Epidemiological investigation revealed that 20%–30% of ICU patients with sepsis had liver dysfunction within 24 hours that can be seen after discharge from hospitals. Moreover, severe patients with sepsis may present with liver-kidney syndrome, liver failure and liver-kidney encephalopathy. As sepsis associated with liver function injury can affect the outcome of septic patients, clinicians should assess liver function of the patients to avoid exacerbation of liver injury during anesthesia and surgery.

Recommendations
1. The assessment of liver function should depend on the levels of bilirubin, alkaline phosphatase, ALT, AST, γ-GGTP, and serum protein in addition to coagulation function (class I).

The blood system
Sepsis may lead to anemia, dysfunction of the coagulation-fibrinolysis system, and even disseminated intravascular coagulation (DIC). Sepsis-induced DIC severely threatens the life of patients, and increases the mortality.

Recommendations
1. Skin color, mucosal color, petechiae, purpura and ecchymoses should be closely monitored to predict the occurrence of severe anemia and coagulation dysfunction (class I).
2. Test of routine blood and coagulation function should be done before surgery. Thrombelastography is recommended as a method for dynamical monitoring of coagulation function if necessary (class I).

The nervous system
Septic patients are viable to develop dysfunction of the nervous system. It has been reported that 70% of patients with sepsis have symptoms of neurological dysfunction, and about 50% have sepsis-associated encephalopathy (SAE). Septic induced brain dysfunction is associated with the overall outcome of the patients.
**Recommendations**

1. Whether the patients have sepsis-induced dysfunction of the nervous system should be determined according to patients' consciousness, cognition, response status and compliance with the instruction (class II).

Sepsis-induced brain dysfunction is due to general inflammatory response, imbalance of oxygen delivery, and consumption of brain tissue. SAE is characterized by acute changes in mental status, impaired attention, agitation, disorientation, alteration of sleep/wake cycle, lethargy and even coma. In septic patients, pathological changes in the brain were seen on imaging, including cytotoxic edema, vasogenic edema, ischemic lesions, white matter disruption and brain atrophy. Sepsis-induced dysfunction of the nervous system not only increased the mortality but also affected the long-term prognosis of patients. Iwashyna et al. found that 17% of septic patients who survived for 3 years suffered from moderate to severe cognitive dysfunction. Therefore, it is necessary to evaluate whether patients have sepsis-induced dysfunction of the nervous system according to their consciousness, cognition, response status, and compliance with the instruction.

**Other assessment and preparation**

Sepsis induces abnormality of glucose metabolism by affecting the endocrine system under inflammatory stress as well as water and electrolyte disorder as a result of liver and kidney dysfunction. Abdominal trauma, infection and intestinal twist and obstruction lead to intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS), which disturb the cardiovascular and respiratory function of septic patients. Thus the relevant symptoms, signs of the patients as well as the results of laboratory examinations should be monitored carefully, and appropriate treatments should be given to correct the abnormality before surgery.

**Recommendations**

1. Blood glucose, water-electrolyte and acid-base balance should be assessed, and appropriate treatments are necessary to correct the abnormality before surgery (class I).

2. To assess the occurrence of IAH and ACS, abdominal pressure should be monitored according to the IAH and ACS Consensus on the Definitions and Clinical Guidelines published by the World Society of Abdominal Compartment Syndrome (WSACS) (class II).

Sepsis can lead to dysfunction of the neuro-endocrine system and increase the excitability of the sympathetic nervous system, resulting in the abnormalities of glucose and lipid metabolism. Blood glucose testing should be done to find the patients with hyperglycemia, and venous insulin should be used reasonably before surgery. RCTs revealed that intensive insulin therapy targeting blood glucose to 80–110 mg/dL did not significantly decrease the mortality of adult patients in the ICU, whereas a large international randomized trial (NICE-SUGAR trial) demonstrated an increased mortality. Additionally, Brunkhorst et al. reported that septic patients did not benefit from intensive insulin therapy, whereas strikingly increased the risk of hypoglycemia. Clinical studies also showed that blood glucose levels >180 mg/dL as the threshold to start an intravenous insulin might be more reasonable for critically ill patients or septic patients.

More studies have been focused on intra-abdominal hypertension. About 60% of septic patients had IAH, which could further develop to ACS if the treatment was inappropriate. In 2013, the WSACS consensus on definition and management of IAH and ACS has been revised. The updated consensus or guidelines recommend that a sustained or repeated intra-abdominal pressure (IAP) > 12 mmHg is defined for the occurrence of IAH, whereas a sustained IAP > 20 mmHg [with or without an abdominal perfusion pressure (APP) > 60 mmHg] for ACS, that is associated with organ dysfunction/failure. Lots of factors are associated with IAH and ACS, including diminished abdominal wall compliance, increased intra-luminal content, increased intra-abdominal content, capillary leak/fluid resuscitation, etc (Table 4). Therefore, it is necessary to evaluate the occurrence of IAH and ACS according to the factors and related examinations, and to monitor IAP if necessary.

**Medical history**

Septic patients are often complicated with chronic diseases such as tumor, coronary heart disease, diabetes and chronic obstructive pulmonary disease. These patients are in a poor physical capacity and immune status, and easily develop complications and organ dysfunction, even severe sepsis and septic shock.

**Recommendations**

1. Medical history of the patients should be assessed in detail. If necessary, experts from other departments should be called for consultation in evaluating the risk of anesthesia and surgery and making a plan for perioperative management (Class II).

In the medical history, tumor, coronary heart disease,
Screening and control of infection source

Control of infection source is the most important treatment of sepsis. Patients with trauma, burn injury and intestinal obstruction/perforation have a definite infectious site, whereas there are also patients with masked focal infection. Therefore, communication between anesthesiologists and surgeons is of great importance on the detailed medical history and tests for assisting to identify the infection source and pathogenic bacteria for early application of antibiotic therapy.

Recommendations

1. Communication between anesthesiologists and surgeons is required to obtain samples of suspicious focal infection for culture before application of first-line anti-microbial agents (class II).

2. Bacteriological examination should be done for the patients who are suspicious of catheter-related infection (arteriovenous catheter, urethral catheter and pleural or abdominal drainage tube) before surgery (class I).

"SSC guidelines" recommend that antibiotics should be prescribed within 1 hour after the diagnosis of sepsis, and bacterial culture should be done before antibiotic therapy.[59] A clinical study demonstrated that early application of antibiotic therapy was associated with decreased mortality of patients with severe sepsis and septic shock.[59] However, because of the emergency surgery of septic patients surgeons may ignore bacterial culture and antibiotic therapy before surgery. Hence, communication is necessary between anesthesiologists and surgeons to ensure the early rational application of antibiotics. Studies showed that 80% of the patients had sepsis caused by hospital acquired infection, and that in these patients catheter-related infection is the main causal factor.[5–5] Thus check tubes should be retained in patients, including arteriovenous catheter, urethral catheter and pleural or abdominal drainage tube. Moreover, bacteriological examination needs to be performed to exclude catheter-related infection.

Preoperative preparation

Perioperative transportation, an important procedure in the management of anesthesia, is associated with the safety of patients.[60] Although septic patients have received basic cardiovascular and respiratory supportive treatment in the early preoperative period, the condition of patients is still vulnerable, especially in the process of transportation to the operating room. Thus, every step in the treatment should be well prepared to guarantee the safety of the patients in the process of transportation.

diabetes and chronic obstructive pulmonary disease are susceptible factors of sepsis that can increase the risk of death. Such patients are always under poor basic conditions resulted from cardiovascular, renal and liver dysfunction before surgery, sepsis can further exacerbate functional injury of related organs and even cause death of the patients.[57,58] Therefore, the detailed medical history should be assessed including history of chronic diseases, current physical capacity, and whether there are organ dysfunction and the severity of sepsis in the preoperative period. In addition, to ensure the safety of patients in the perioperative period, other related departments should be called for consultation in evaluating the risk of anesthesia and surgery and making a plan of perioperative management if necessary.
Recommendations
1. Continuous monitoring is needed for the patients during the process of transportation, and attention should be paid to the handover of personnel, facilities and drugs (class I).

When septic patients are transported to operation room they should be subjected to persistent monitoring of oxygenation status, blood pressure, heart rate, etc. Communication between surgeons and anesthesiologists is beneficial for the preoperative preparation. The individuals responsible for transportation, persistent monitoring and handover of personnel, facilities and drugs are important for the safety of patients during the process of transportation.

ANTRAOPERATIVE MONITORING AND MANAGEMENT
Septic patients are usually complicated with tumor, chronic pulmonary diseases, cardiovascular and cerebrovascular diseases and intake of immunosuppressive drugs. Since septic patients usually undergo emergency surgery and frequently have circulatory failure, respiratory dysfunction or other organ dysfunction, more attention should be paid to anesthetic methods and agents.

Anesthetic methods
Patients with sepsis always have a poor physical condition at the time of operation, and exhibit complicated pathophysiological changes. Hence anesthesia should be given carefully to these patients.

Recommendations
1. Local infiltration anesthesia, regional blocking anesthesia, and general anesthesia are feasible in septic patients, but they should be selected individually after preoperative evaluation (class I).
2. Intravertebral anesthesia is not suitable for septic patients if their hemodynamics is not stable (class II).
3. Reflux and aspiration must be avoided in patients with full stomach (class II).

Almost all the expert anesthesiologists agreed that local infiltration anesthesia, regional blocking anesthesia and general anesthesia are available for septic patients. The most appropriate anesthetic method was selected for the patient according to surgical site, surgical type, scope of surgery and operative time. In 1992, Carp et al reported that spinal block increased the risk of infection of the central nervous system in septic rats. Furthermore, intravertebral anesthesia, especially spinal block, greatly influenced the hemodynamics because of the blocking of the sympathetic nervous system, which could result in deterioration of circulatory failure of septic patients. Thus, intravertebral anesthesia is not recommended for septic patients with instable hemodynamic. Septic patients with gastrointestinal perforation, intestinal obstruction or infection of the biliary tract are subjected to emergency surgery and in whom attention should be paid to the prevention of reflux and aspiration.

Anesthetic drugs
Septic patients are often complicated with circulatory instability and damage to the liver and kidney. Hence in the process of anesthetic induction and maintenance, the effect of anesthetics on circulatory function as well as the liver and kidney burden should be considered.

Recommendations
1. Titration method of drug delivery is recommended in the process of anesthetic induction to avoid hemodynamic fluctuation (class I).
2. Midazolam, propofol, ketamine and etomidate as intravenous anesthetics are suitable for septic patients, but etomidate is not indicated for patients with adrenal insufficiency (class II).
3. Fentanyl, sufentanil and remifentanil as opioid analgesics are suitable for septic patients (class I).
4. Cisatracurium, atracurium, rocuronium and vecuronium as muscle relaxants are suitable for septic patients (class II).
5. N₂O, isoflurane, sevoflurane and desflurane as volatile anesthetics are feasible for septic patients, but N₂O is not indicated for patients with pneumothorax or intestinal obstruction (class II).
6. Dexmedetomidine as an adjuvant is indicated for septic patients during anesthetic induction and maintenance (class II).

Anesthetics including sedative drugs and opioid analgesics are effective in inhibiting cardiac function and relaxing vessels. Titration method of drug delivery is can reduce the disturbance of hemodynamic. Midazolam is a member of benzodiazepines which has the effect of sedation, hypnosis and anterograde amnesia, and it is often used to prevent intraoperative awareness. Based on the slight effect on the circulation, ketamine and etomidate are more suitable for septic patients. Although etomidate can inhibit the function of adrenal cortex, clinical studies demonstrated that single-dose
etomidate could not influence the outcome of septic patients. Ketamine, another safe and valuable agent for endotracheal intubation, does not increase the risk of side-effect in septic patients. Although animal studies showed that propofol could significantly inhibit myocardial and circulatory function, Tang et al. found that propofol has a beneficial effect on the regulation of inflammatory response. Thus we must be careful when propofol is used in septic patients. It is necessary to adopt the titration method, starting from a low dosage while adjusting it slowly according to the response of the patients. At present, there is no clinical evidence indicating that inhalation anesthesia is beneficial for patients with sepsis. Schilling et al. found that volatile anesthetics could improve the outcome of patients with ischemia-reperfusion injury who had undergone cardiac surgery. Dexmedetomidine has the effect of sedation and inflammatory regulation, which could reduce the prevalence of delirium in critical ill patients. It is feasible as an adjuvant for septic patients to decrease the dosage of other anesthetics.

Intraoperative monitoring
Besides routine monitoring, it is necessary to monitor the organ function, tissue perfusion and depth of anesthesia for septic patients in the perioperative period.

Recommendations
1. Routine monitoring including electrocardiogram, blood pressure, \( \text{SpO}_2 \), \( \text{P}_{\text{ET}} \text{CO}_2 \), pressure of airway, respiratory waveform, body temperature and urine output should be used for septic patients (class I).
2. Invasive blood pressure and central venous pressure should be monitored for patients with hemodynamic instability (class I).
3. FloTrac, PICCO, Swan-Ganz and cardiac ultrasound could be used for septic patients, and the parameters of stroke volume variation (SVV), pulse pressure variation (PPV), cardiac index (CI), and corrected flow time (FTc) could be used to guide fluid therapy during the operation (class II).
4. Blood glucose, arterial blood gas, blood lactate, blood routine, blood electrolyte, coagulation function, BNP and troponin should be monitored during the operation (class I).
5. The depth of anesthesia and muscle relaxation should be monitored during the operation (class II).

Management of the circulatory system
The evaluation of volume status and cardiac function is essential to the management of the circulatory system in septic patients during the operation. The strategy of EGDT including fluid challenge, blood transfusion and use of vasoactive agents would benefit septic patients.

Recommendations
1. The first objective of fluid management: MAP\( \geq 65 \) mmHg, CVP 8–12 mmHg, urine output\( \geq 0.5 \text{ mL/kg per hour} \), arterial blood lactate\( <4.0 \text{ mmol/L} \) (class I).
2. The second objective of fluid management: ScvO\( _2 \) \( \geq 70\% \) or SvO\( _2 \) \( \geq 65\% \) (class III).
3. Crystalloid solution such as acetated Ringer's solution or lactated Ringer's solution was recommended as the first-choice fluid for septic patients, whereas hydroxyethyl starch was not recommended as a treatment for patients with severe sepsis during the operation. If it is inevitable to use colloid solution, albumin is suggested as the first choice (class II).
4. Norepinephrine is used as the first-choice vasopressor, then epinephrine, vasopressin, dopamine, dobutamine and phenylephrine could be used according to the condition of septic patients (class I).
5. Fresh frozen plasma (FFP) is not applicable for the increase of blood volume in septic patients (class II).
6. Platelet count should be beyond \( 50 \times 10^9/\text{L} \) during the operation (class II).
7. The level of hemoglobin should be beyond \( 70 \text{ g/L} \) during the operation (class II).
8. Intravenous hydrocortisone at a dose of 200 mg per day is prescribed as a treatment for septic patients when adequate fluid resuscitation and vasopressor therapy fail to restore stable hemodynamics (class II).

Clinical studies found that EGDT did not
reduce the mortality of patients with severe sepsis. However, since EGDT was incorporated into 2004 "SSC guidelines", the mortality of patients with sepsis has decreased in the recent decades. Prospective retrospective studies also showed that adherence of "SSC guidelines" could improve the outcome of sepsis. Thus, EGDT is recommended as a fluid management for septic patients during the operation. The optimal target to evaluate the effect of fluid management is still worth investigating. Clinical studies demonstrated that lactate clearance is an effective parameter to evaluate the fluid management of septic patients. The "SSC guidelines" also recommended that the recovery of blood lactate serves as a target of fluid management of septic patients. Recently, Asfar et al. found that high blood pressure (MAP 80–85 mmHg) did not improve the outcome of septic patients, but reduced the rate of the renal replacement therapy in the patients who had hypotension before surgery. It is still difficult to decide which one is the best fluid for septic patients. Clinically, crystalloid solution such as acetated Ringer's solution or lactated Ringer's solution was recommended as the first-choice fluid, whereas hydroxyethyl starch was not used for the treatment of patients with severe sepsis. A large dose of crystalloid solution was detrimental to the recovery of patients after the operation. Therefore 5% albumin is recommended as the first-choice for the treatment of patients who have to use colloid solution. The 2012 "SSC guidelines" suggest norepinephrine as the first-choice vasopressor. Epinephrine, vasopressin, dopamine, dobutamine and phenylephrine could be prescribed according to the condition of patients when an additional agent is needed to maintain adequate blood pressure. FFP is recommended as a treatment for abnormal coagulation function, but not for regular fluid management. During the operation, platelet count should be maintained beyond 50×10⁹/L. Up to present, there is no investigation specifically on the optimum concentration of hemoglobin in patients with severe sepsis. However, a clinical trial suggested that a hemoglobin level of 70–90 g/L, compared with 100–120 g/L, was not associated with increased mortality in critically ill adult patients. Another randomized trial in patients undergoing cardiac surgery with cardiopulmonary bypass also showed a restrictive transfusion using a threshold of hemoglobin 80 g/L as equivalent to a transfusion threshold of hemoglobin 100 g/L. Several RCTs showed that the response of septic shock patients to fluid and vasopressor therapy seems to be an important factor in selecting patients for optional hydrocortisone therapy. Intravenous hydrocortisone at a dose of 200 mg/day could improve the outcome of septic patients who have failed to restore hemodynamic stability after adequate fluid resuscitation and vasopressor therapy.

**Management of the respiratory system**

Lung protective ventilation (LPV) could improve the outcome of patients with ARDS, and this ventilation is also suitable for septic patients during operation.

**Recommendations**

1. LPV is a treatment for septic patients with ARDS (including low tidal volume, PEEP and lung recruitment maneuver, etc.) (class I).

Sepsis commonly induces the dysfunction of the respiratory system. Clinical studies showed that LPV such as low tidal volume (6 mL/kg) and plateau pressure ≤30 cmH₂O can significantly reduce the mortality of septic patients with ARDS. Studies also showed that low tidal volume (7 mL/kg), PEEP (10 cmH₂O) and lung recruitment maneuver could significantly improve respiratory function, shorten the length of hospital stay, and improve the outcome of patients after a major abdominal surgery.

**Regulation of the immune system**

Sepsis is a complex syndrome caused by a variety of diseases. The imbalance of immune and inflammatory response is the main pathophysiological mechanism of sepsis. The treatment of regulating immunity and inflammation would be beneficial to septic patients during operation.

**Recommendations**

1. Intravenous injection of immunoglobulin is not suitable for septic patients during operation (class II).

Intravenous injection of ulinastain is suitable for the treatment of septic patients during operation (class II).

3. Subcutaneous injection of thymosin and intravenous drip of Xuebijing could be used as a treatment for septic patients during operation (class III).

Large multicenter RCTs in septic patients demonstrated that there is no benefit for intravenous injection of immunoglobulin (IVIG). Ulasmastain is a kind of protease inhibitor, which can stabilize the lysosome membrane, inhibit the release of lyosomal enzyme, eliminate oxygen radicals, and reduce the
inflammatory response. Animal and clinical studies showed that ulinastatin improved the outcome of surgical patients and septic patients via regulating oxidative stress and inflammatory response. A meta-analysis also found that the intraoperative use of ulinastatin could shorten mechanical ventilation time in the patients with extracorporeal circulation surgery. Recently, Karnad et al have confirmed that ulinastatin can reduce the incidence of organ dysfunction, shorten mechanical ventilation time, and improve the outcome of septic patients. Thymosin is a group of small molecular peptides secreted by the thymus tissue, which can strengthen the immune function of the host, and has been used as a treatment for patients with viral hepatitis, immune deficiency disorders, and chemotherapy. In the treatment of sepsis, Wu et al found that subcutaneous injection of thymosin alpha 1 reduced the mortality of septic patients. Additionally, a meta-analysis also revealed that thymosin obviously improved the outcome of patients with sepsis. Xuebijing, a traditional Chinese medicine preparation, has functions of anti-inflammation, neutralizing endotoxin and regulating immune cells, etc. Animal experiments showed that Xuebijing reduced the mortality of septic mice. A single center clinical study found that Xuebijing could promote the stabilization of hemodynamics and improve the outcome of patients with sepsis complicated with DIC. Furthermore, Zhang et al and Li et al found that immunomodulatory therapy that combines thymosin alpha 1 and ulinastatin improved the survival rate of patients infected with carbapenem-resistant bacteria. However, these studies are done by single centers and the sample size is small, hance large RCTs are needed to elucidate the effect of immunomodulatory therapy combined with two or more agents in the treatment of septic patients.

TREATMENT IN INTENSIVE CARE UNIT

Postoperative management is very important for septic patients. If hemodynamics was stable without organ dysfunction, it is advisable to transfer the patients to the post anesthesia care unit (PACU) after surgery. However, if the patients are associated with severe chronic diseases, unstable breathing and circulation or other vital organ dysfunction, it is imperative to transfer the patients to the ICU for advanced treatment. The “SSC guidelines” have been revised twice based on large RCTs since 2004. The present consensus focuses on the anesthesia-associated management during the perioperative period. Thus we suggest the 2012 “SSC guidelines” for the treatment in the ICU.

Recommendations

1. Patients with severe sepsis and septic shock should be transferred to the ICU for advanced treatment after surgery (class I).

List of recommendations

(Class I-V: class I is the strongest recommendation, class V is the weakest recommendation.)

</tbody>
</table>
**Liver function**
1. Liver function assessment is based on the level of bilirubin, alkaline phosphatase, ALT, AST, γ-GGTP, serum protein and coagulation function.

**The blood system**
1. Skin color, mucosal color, petechiae, purpura and ecchymoses should be closely monitored to predict the occurrence of severe anemia and coagulation dysfunction.
2. Testing of routine blood and coagulation function should be done before surgery. Thrombelastography is used to dynamically monitor coagulation function if necessary.

**The nervous system**
1. Whether patients have sepsis-induced dysfunction of the nervous system is determined according to their consciousness, cognition, response status and compliance with the instruction.

**Other assessment and preparation**
1. Blood glucose, water-electrolyte and acid-base balance should be assessed, and appropriate treatments are given to correct the abnormality before surgery.
2. To assess the occurrence of IAH and ACS, abdominal pressure should be monitored according to IAH and ACS Consensus Definitions and Clinical Guidelines published by the World Society of Abdominal Compartment Syndrome (WSACS).

**Medical history**
1. Medical history of the patients should be assessed in detail. If necessary, other departments should participate in evaluating the risk of anesthesia and surgery and making a plan of perioperative management.

**Screening and control of infection source**
1. Communication between anesthesiologists surgeons is necessary to obtain samples of suspicious focal infection for culture before a first-line anti-microbial treatment.
2. Bacteriological examination should be done for the patients who are suspicious of catheter-related infection (arteriovenous catheter, urethral catheter and pleural or abdominal drainage tube) before surgery.

**Preoperative preparation**
1. Continuous monitoring is necessary for the patients during the process of transportation, and attention should be paid to the handover of personnel, facilities and drugs.

**Intraoperative monitoring and management**

**Anesthetic methods**
1. Local infiltration anesthesia, regional blocking anesthesia and general anesthesia are suitable to septic patients, which should be selected individually after preoperative evaluation.
2. Intravertebral anesthesia is not suitable for septic patients if their hemodynamics is instable.
3. Reflux and aspiration should be avoided in the patients with full stomach.

**Anesthetic agents**
1. Titration method of drug delivery is used in the process of anesthetic induction to avoid hemodynamic fluctuations.
2. Midazolam, propofol, ketamine and etomidate as intravenous anesthetics are suitable for septic patients, but etomidate is not indicated for patients with adrenal insufficiency.
3. Fentanyl, sufentanil and remifentanil as opioid analgesics are suitable for septic patients.
4. Cisatracurium, atracurium, rocuronium and vecuronium as muscle relaxants are suitable for septic patients.
5. N2O, isoflurane, sevoflurane and desflurane as volatile anesthetics are feasible for septic patients, but N2O is not indicated for patients with pneumothorax or intestinal obstruction.
6. Dexmedetomidine as an adjuvant agent is indicated for septic patients during anesthetic induction and maintenance.

**Recommendations**

**Liver function**
1. Routine monitoring including electrocardiogram, blood pressure, SpO2, PETCO2, pressure of airway, respiratory waveform, body temperature and urine output is necessary for septic patients.
2. Invasive blood pressure and central venous pressure should be monitored for patients with hemodynamic instability.
3. FloTrac, PiCCO, Swan-Ganz and cardiac ultrasound could be used for septic patients, and the parameters of stroke volume variation (SVV), pulse pressure variation (PPV), cardiac index (CI), and corrected flow time (FTc) can be used to guide fluid therapy during operation.
4. Blood glucose, arterial blood gas, blood lactate, blood routine, blood electrolyte, coagulation function, BNP and troponin should be monitored during operation.
5. Depth of anesthesia and muscle relaxation should be monitored during operation.

**Management of the respiratory system**
1. The first objective of fluid management: MAP≥65 mmHg, CVP 8–12 mmHg, urine output≥0.5 mL/kg per hour, arterial blood lactate<4.0 mmol/L.
2. The second objective of fluid management: ScvO2≥70% or SvO2≥65%.
3. Crystalloid solution such as acetated Ringer's solution or lactated Ringer's solution can be used as the first-choice fluid for septic patients, whereas hydroxyethyl starch is not used for the treatment of patients with severe sepsis during operation. If colloid solution is available, albumin could be used as the first choice.
4. Norepinephrine can be used as the first-choice vasopressor, then epinephrine, vasopressin, dopamine, dobutamine and phenylephrine could also be used according to the condition of the patient.
5. Fresh frozen plasma (FFP) is not applicable for the increase of blood volume in septic patients.
6. Platelet count should exceed 50×10^9/L during operation.
7. The level of hemoglobin should exceed 70 g/L during operation.
8. Intravenous hydrocortisone at a dose of 200 mg per day is prescribed as a treatment for septic patients when adequate fluid resuscitation and vasopressor therapy fail to restore the stable hemodynamics.

**Regulation of the immune system**
1. Intravenous immunoglobulin is not suitable for septic patients during operation.
2. Intravenous ulinastain is suitable for the treatment of septic patients during operation.
3. Subcutaneous injection of thymosin and intravenous drip of Xuebijing could be used for the treatment of septic patients during operation.

**Treatment in intensive care unit (ICU)**
1. Patients with severe sepsis and septic shock should be transferred to the ICU for advanced treatment after surgery.
