BACKGROUND: In 2013 a General Practitioner Cooperative (GPC) was introduced at the Emergency Department (ED) of our hospital. One of the aims of this co-located GPC was to improve throughput of the remaining patients at the ED. To determine the change in patient flow, we assessed the number of self-referrals, redirection of self-referrals to the GPC and back to the ED, as well as ward and ICU admission rates and length of stay of the remaining ED population.

METHODS: We conducted a four months' pre-post comparison before and after the implementation of a co-located GPC with an urban ED in the Netherlands.

RESULTS: More than half of our ED patients were self-referrals. At triage, 54.5% of these self-referrals were redirected to the GPC. After assessment at the GPC, 8.5% of them were referred back to the ED. The number of patients treated at the ED declined with 20.3% after the introduction of the GPC. In the remaining ED population, there was a significant increase of highly urgent patients (P<0.001), regular admissions (P<0.001), and ICU admissions (P<0.001). Despite the decline of the number of patients at the ED, the total length of stay of patients treated at the ED increased from 14 682 hours in the two months' control period to 14 962 hours in the two months' intervention period, a total increase of 270 hours in two months (P<0.001).

CONCLUSION: Introduction of a GPC led to efficient redirection of self-referrals but failed to improve throughput of the remaining patients at the ED.

KEY WORDS: Emergency Service, hospital; General practitioners; Crowding; Length of stay

INTRODUCTION
Emergency department (ED) crowding is an increasingly recognised problem that affects hospitals all over the world.[1-12] Causes for ED crowding include input causes (such as the increase in ED presentations),[1] throughput causes (such as waiting times for diagnostics), and output factors (such as lack of inpatient capacity).[4] While output factors are considered to be the most important cause of ED crowding,[5] e.g. waiting for an inpatient bed,[6] the growing number of visits by so called self-referrals with minor problems who could be seen by a general practitioner (GP) is also of concern for EDs.[7,8] The organization of out-of-hour services in primary care has changed, with new models such as large GP cooperatives (GPCs) and primary care centres integrated into EDs.[9-11]

In the Netherlands, the proportion of self-referrals at EDs is approximately 30%.[13] Almost all Dutch citizens have a GP and basic health insurance. GPs are obliged to organise a 24-hour care system of availability, in which both regular and acute care is provided during office hours and only acute care after hours. Some patients bypass their GP and present to the ED directly.[13] Reasons for self-referrals for bypassing their GP are, amongst many other reasons, the EDs' easy access and the perceived need for hospital emergency care, e.g. the need for an X-ray.[13]
To prevent patients from self-referring to the ED, GPs in the Netherlands have reorganised out-of-hours primary care from small practices into large GPCs co-located with EDs. In the study setting, a GPC was introduced in February 2013.

This paper describes what happened after the introduction of the GPC. It was assumed that the number of patients at the ED would decline when self-referrals with minor problems would be guided to the GPC. At the same time, there were concerns that time- and money consuming double consults would occur for a part of the self-referrals. Furthermore, it was assumed that redirecting a part of the patients to the GPC would have a positive impact on throughput times of the remaining patients at the ED.

The objectives of this study were to answer the following questions: (1) How many self-referrals are redirected from the ED to the GPC? (2) How many of these self-referrals are referred back to the ED after treatment at the GPC? (3) Are there signs of improved throughput of the remaining ED patient population?

METHODS
Design
A pre-post comparison before and after the implementation of a co-located GPC with an inner- city, level one trauma centre in the Netherlands with approximately 52 000 patient visits annually. The answers to questions one and two were calculated during the intervention period (October and November 2013). For the answer to question three, total length of stay (LOS), patients' acuity level and admission rate) of the ED patients were compared between the intervention period (October and November 2013) and a control period (October and November 2012).

The objectives of this study were to answer the following questions: (1) How many self-referrals are redirected from the ED to the GPC? (2) How many of these self-referrals are referred back to the ED after treatment at the GPC? (3) Are there signs of improved throughput of the remaining ED patient population?

Procedures and data collection
The ED uses the Manchester Triage System (MTS), a five-point scale, to assess acuity level. An extension in the MTS helps the triage nurse to identify patients eligible for treatment at the GPC. This extension was a consensus-based effort of GPs and hospital based specialists and triage nurses.

Data were retrieved from the hospitals' electronic patient database (ChipSoft, Amsterdam, the Netherlands). Data collected included demographic details (gender, age), arrival time, type of complaint, acuity level, discharge time, and disposition. Patients' LOS was defined as the interval between patients' arrival and the moment the patient left the ED.

Analysis
Descriptive analyses were conducted to describe patients' characteristics. Differences between the period before (control period) and period after (intervention period) the GPC implementation were analysed using χ²-tests (gender, age groups, acuity level, and disposition) and the Mann-Whitney U-tests (LOS). A P<0.05 was considered statistically significant. Data analysis was performed using Statistical Package for the Social Sciences (SPSS, version 22, Chicago, Illinois, USA).

RESULTS
During the two-month intervention period, 8 311 patients were registered at the ED. More than half of these patients were self-referred (4 372, 52.6%).

At triage, 1 989 (45.5%) of the self-referrals were redirected to the GPC. The remaining self-referrals (2 383, 54.5% of the self-referrals) were triaged to the ED.

Of all patients who were redirected to the GPC at triage, 169 (8.5%) patients needed specialist emergency care and were referred to the ED. These were mainly patients with limb problems with suspected bone fracture, and patients with abdominal complaints and an elevated CRP.

The number of patients treated at the ED declined with 20.3% compared to the control period (control period: 7 936 patients vs. 6 322 patients in the intervention period (Table 1). At the same time, there was a significant increase in referred patients during the intervention period.

DISCUSSION

This study carried out with a before and after intervention design showed that almost half of our ED patients were self-referrals, and of those self-referrals, more than half were redirected to the GPC. The introduction of the co-located GPC with our ED resulted into a 20% reduction of ED patients. Despite the decline of the number of patients at the ED, there was no improved throughput of the remaining patients at the ED.

The self-referral rate at this urban hospital ED was 52.6%. This is high compared to the median percentage in the Netherlands, which is 30%.\(^\text{[12]}\) This discrepancy might be explained by differences between hospitals in the population health status, and differences in the organization of the GP-services. Also, patients living in highly urbanised areas more commonly bypass their GPs.\(^\text{[12]}\)

Self-referrals are believed to present with minor problems that should be treated by their GP. However, in our study only half of the self-referrals were redirected to the GPC. This may be partly due to the triage-methodology, partly to the GPs’ lack of access to radiography, EKG and blood tests, and partly to the fact that some self-referrals have urgent problems.\(^\text{[13]}\)

Only 8.5% of self-referrals directed to the GPC were referred back to the ED because they needed hospital emergency care. This low percentage probably does not justify the concerns for time- and money-consuming double consults. A prospective cost-effectiveness study is needed to confirm this. On the other hand, when considering the implementation of a GPC co-located with an ED, there is little evidence to support overall cost-effectiveness. Although marginal savings per patient may be realized, this is likely to be overshadowed by the overall cost of introducing a new service.\(^\text{[15]}\)

In some other studies, the introduction of a co-located GPC with an ED has failed to reduce attendances.\(^\text{[15,16]}\) Our study contradicts these findings: 20% of our patients were referred to the GPC. Unfortunately, there were no signs of an improved throughput for the remaining patients at the ED. The latter is supported by other studies, the evidence for improved throughput when co-locating GPCs at EDs is poor.\(^\text{[15,17]}\)

As said, the number of patients assessed and treated at the ED decreased with 20%. At the same time, the caseload at the ED changed significantly. More referred patients by GPs, by ambulances, and by medical specialists, an increase in acuity levels, and a higher admission rate indicate a significant change in the workload of this ED. These findings coincide with a previous study.\(^\text{[9]}\) Obviously, more complex patients lead to increased LOSs, more inpatient admissions, and less inpatient capacity, which in turn cause increased workload and ED crowding.\(^\text{[5]}\) A future study objectifying the effects of a co-located GPC with the ED would be of interest.

Limitations

In this study, we found that self-referrals were adequately triaged to the GPC and reduced patient volume. We also found an increase in the number of referred patients requiring more attention. Because of our pre- post design, we cannot prove a relationship between the two findings. In general, referred patients are more urgent and have higher admission rates as compared to
self-referred patients.\textsuperscript{13} Although the increase in ED patients who were referred by a GP seems associated with the location of the GPC at the ED, it is hard to prove causality since unknown external factors could play a role. Thus, the finding that the caseload at the ED changed significantly after the implementation of the GPC should be considered with great caution and warrants further research.

Second, we worked with computerised data. Data entry inaccuracies in the system could have biased the results. However, it is unlikely that inaccuracies were unequally divided over the different periods investigated.

Finally, this study conveys the experience of a single hospital and may have limited generalizability because of the characteristics of our population and differences in health care delivery. Nonetheless, we hope that our study can contribute towards a growing body of research that aims to understand the impact of introducing a co-located GPC with an ED.

In summary, our study adds further evidence that the implementation of a GPC can contribute to the delivery of efficient health care for a part of the self-referrals at an ED. However, despite a 20% decrease in total number of patients, LOS of remaining patients at the ED increased, probably due to a change in patient population. The ED caseload changed, with more referred, complex patients while having less patient visits in total.
